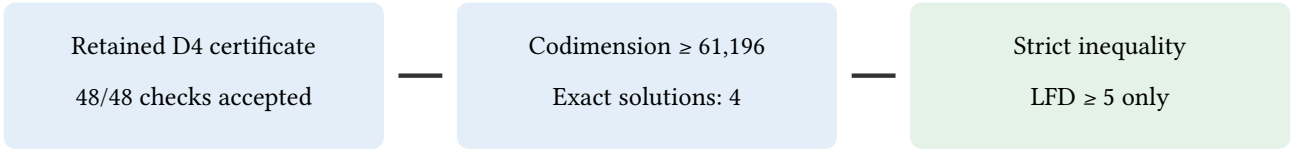
n47 random02 certificate recovery

Independent recovery accepted the retained n=47 random-subspace instance 02 degree-four certificate. All 48 multiplication checks passed. The checker establishes codim W4 ≥ 61,196; the fresh exhaustive solution count is 4. The strict inequality establishes LFD ≥ 5. It establishes neither a degree-six lower bound nor an upper bound.

This is a validation recovery of an interrupted attempt, not a new random draw. The original attempt remains unchanged and has no terminal cascade result. The original 47-input campaign still has seven terminal inputs and forty unfinished inputs; this recovery must not be counted as an eighth completed cascade.

Evidence snapshot: commit 072a3588d5, ../../runs/highmem-rand02-check-recovery-001/result.json, check4.stdout.txt, count.stdout.txt, and started.json. Exact commands and caps are in the step records. The retained certificate has 1,632,838,224 bytes and SHA256 fc6758d954e680280bc6ef4c2ce3a051401a2a87a3c7e6b8babfdb32bc1a66cb. All nine supporting artifact hashes and the complete certificate hash were verified after completion.

The independent checker returned zero after 1,002.62 seconds and the counter returned zero after 11.21 seconds. These are shared-host L0 operational observations; wall_valid is false. No performance comparison is claimed. The checker had a 4 GiB address-space cap, the counter 1 GiB, with a six-hour watchdog. The recovery reused the original checker and frozen input, with no algebraic algorithm change or new comparative controls.


The recovery source is commit 88178a38a8d149cc09d674d89e223e48adb5865a; the launch receipt and recovery plan bind the script and checker hashes. Public archive publication is pending at this report snapshot. The diagram records this accepted evidence chain only; no canonical mathematical graph changes because the result is another instance of the existing certificate implication.
