Blocked rewrite with native checkpoints

28 of 28 actual configurations passed. Seven retained fixtures were run in reference, fresh blocked, deliberately stopped blocked, and restored blocked modes. Completed certificates must match retained reference SHA-256 values and pass the independent generic polynomial conditions or original Semaev checker. Source rows deliberately exit 75 after two complete checkpoints and do not produce certificates.

Nonempty checkpoint coverage: True. This tests the combination of the existing block rewrite, bounded export and native checkpoint code. The source commit is 6de5b719586b69c1749041099b2aca533978b1d4. The frozen protocol hash is fe16564ff63c8d21d93e8a07d5b3d364f6583986974b0d5c91c52e578cf7ee9a.

This is native software integration evidence only. It establishes no new mathematical bound, measured speed advantage, frontier memory admission or cloud-worker qualification. Binary identity is part of the checkpoint: the new binary cannot restore snapshots made by the old binary. Existing frontier and panel jobs remain separate.

All rows and failures are retained without retries or exclusion. The mathematical-bound graph is unchanged because these are retained small fixtures. The outcome diagram records actual control outcomes.
